Abstract

We consider the spin-exchange in ultracold collisions of hydrogen (H) and antihydrogen ($\bar{H}$) atoms. The cross sections for transitions between various hyperfine states are calculated. We show that the process of spin exchange in $\bar{H} - H$ collisions is basically driven by the strong force between proton and antiproton, that spin-exchange cross-sections are proportional to the difference of singlet and triplet strong force S-wave scattering lengths, while the strong force effects are enhanced about 10^9 times due to long range atomic forces. We show that any difference in hyperfine structure of H and $\bar{H}$ (CPT violation) manifests itself in radical change of spin-exchange cross-sections energy behavior.

1 Introduction

The successful production of low energy antihydrogen atoms [1, 2] and current experiments on their trapping [3, 4] have stimulated interest in the interaction of antiatoms with ordinary matter. The simplest example of matter-antimatter interaction is given by collisions between antihydrogen and hydrogen atoms [5, 6, 7, 8, 9, 10, 11, 12]. Collisions between antihydrogen and helium atoms have also been studied [13]. These investigations revealed that cold collisions between atoms and antiatoms do not necessarily result in annihilation, but may lead to elastic scattering or rearrangement reactions. Interestingly, it was shown that the cross sections for processes that do *not* result in annihilation (e.g. elastic scattering) are sensitive to the strong interaction between particles and antiparticles [14, 13, 15, 12, 16, 17]. This presents an interesting perspective for investigating the details of strong interactions between matter and antimatter in low energy collisions of atoms and antiatoms.

In the present work we investigate spin exchange in hydrogen-antihydrogen collisions. The oncoming atoms are assumed to be asymptotically in the well defined hyperfine states which can be changed as the result of collisions. This can happen with or without changing the internal energy of the individual atoms so that some of these collisions appear elastic, apart from spin-flip. We find that in the case of $H - \bar{H}$ scattering the main source of such spin-exchange transitions is the *strong force*. This is in contrast to spin-exchange in atom-atom collisions (see [18, 19] and the references therein), where the strong-force effects are usually negligible. At the same time the leptonic contribution to spin-exchange in $H - \bar{H}$ collisions is found negligibly small, in spite of the fact that the magnetic moments of the leptons (electron (e) and positron ($\bar{e}$)) are on the order of 10^3 times larger than those for the hadrons (proton (p) and antiproton ($\bar{p}$)). We will show that long range van der Waals interactions between atoms and antiatoms plays role of magnifying glass that exposes the strong force effects on the molecular scale. Another unique feature of the spin-exchange cross sections is their sensitivity to the equality of the hyperfine energy levels in H and $\bar{H}$, ensured by the CPT invariance. Violation of that invariance results in a radical change of certain cross sections for spin-exchange.

The paper is organized as follows. In section 2 we present the formalism used in calculating spin-exchange cross sections. Section 3 discusses the main results. The physical sense of these results is analysed in terms of a transparent zero-range potential model of strong forces. Section 4 contains the conclusions and the Appendix gives the details of certain derivations.

2 Formalism

We assume the following four-body Hamiltonian for the $H\bar{H}$ system:

$$\hat{H} = \hat{H}_{nr} + \sum_{\alpha} \hat{W}_{\alpha}(\mathbf{s}_{\alpha}, \mathbf{r}_{\alpha}). \quad (1)$$

Here $\hat{H}_{nr}$ is the nonrelativistic spin-independent Hamiltonian, which includes the kinetic and Coulomb interaction energy for all particles. The subscript α labels the pairs of interacting particles: $(p\bar{p})$, (pe) , $(p\bar{e})$, $(\bar{p}e)$, $(\bar{p}\bar{e})$ or $(e\bar{e})$. $\hat{W}_{\alpha}(\mathbf{s}_{\alpha}, \mathbf{r}_{\alpha})$ is the spin-dependent pair interaction, arising from low order relativistic corrections to the nonrelativistic Hamiltonian; $\hat{W}_{\alpha}(\mathbf{s}_{\alpha}, \mathbf{r}_{\alpha})$ acts on the spin $\mathbf{s}_{\alpha}$ and the relative coordinates $\mathbf{r}_{\alpha}$ of the particle pair α .

The forthcoming analysis can be greatly simplified by taking into account the characteristic spatial and energy scales of the interactions involved in $H - \bar{H}$ scattering. As pointed out in [20, 21, 22, 5, 23, 6, 7, 24, 25], the rearrangement transitions to Protonium (Pn) and Positronium (Ps) occur mainly at internuclear distances smaller than the rearrangement radius $R_r \simeq 1$ a.u.. For internuclear distances above R_r the adiabatic approximation, leading to the separation of leptonic and hadronic motion, is well justified. This allows the description of ultralow energy $H - \bar{H}$ scattering within a one-channel model based on a nonrelativistic Hamiltonian [8, 23, 24]:

$$\hat{H}_{nr} \simeq \hat{T}_{kin} + \hat{V}_{opt} + V_{ad}(R). \quad (2)$$

The above Hamiltonian describes the interatomic motion in a fixed adiabatic leptonic state, where $\hat{T}_{kin}$ is the operator of kinetic energy of internuclear motion, $V_{ad}(R)$ is the adiabatic potential in a given leptonic state, and $\hat{V}_{opt}$ is the effective complex optical potential that accounts for the inelastic rearrangement and vanishes for interatomic distances $R > R_r$.

In the following we will discuss the ultralow energy collisions of H and $\bar{H}$ in the ground leptonic state. We will use the adiabatic interaction potential $V_{ad}(R)$ obtained in [26]. It is worth noting that since the Pauli principle is not forbidding an electron and a positron to occupy identical spin-space states, the adiabatic potential $V_{ad}(R)$ is independent of the leptonic spin state. This is in contrast to the case of HH , where due to the Pauli principle the adiabatic potential is different in singlet and triplet electronic states. This difference is important for our considerations. In fact, the spin-exchange transitions in $H - \bar{H}$ collisions can occur only when the (*relativistic*) spin-dependent terms $\bar{W}_\alpha(\mathbf{s}_\alpha, \mathbf{r}_\alpha)$ are taken into account. At the same time in the HH case the main contribution to such transition rates comes from the above mentioned effective spin dependence of the *nonrelativistic* adiabatic potential, while the explicitly spin-dependent interaction appears as a perturbation. We will show in the following that the spin-exchange reactions in $H - \bar{H}$ collisions are particularly sensitive to the spin dependent strong force between proton and antiproton.

The general form of the spin-dependent interaction is:

$$\widehat{W}_\alpha = W_\alpha^0(r_\alpha) + W_\alpha^1(r_\alpha)(\mathbf{L}_\alpha \mathbf{S}_\alpha) + W_\alpha^{2a}(r_\alpha)(\mathbf{r}_\alpha \mathbf{S}_\alpha)^2 + W_\alpha^{2b}(r_\alpha) \mathbf{S}_\alpha^2. \quad (3)$$

In the above formula $\mathbf{r}_\alpha$, $\mathbf{L}_\alpha$, $\mathbf{S}_\alpha$ are relative coordinate, angular momentum and spin operators for the particle pair α .

The particular form of the lepton-lepton and lepton-hadron pair interactions can be obtained within the QED [27]. In the case of (pe) and $(\bar{p}\bar{e})$ they are responsible for the hyperfine splitting of the ground state of hydrogen and antihydrogen. In the present work we will approximate the non-relativistic pair interactions for (pe) and $(\bar{p}\bar{e})$ by the following effective terms [18]:

$$\widehat{W}_{(ep),(\bar{e}\bar{p})} = a_{HF}(\mathbf{s}_{e,\bar{e}} \mathbf{i}_{p,\bar{p}}) = \frac{a_{HF}}{2}(\mathbf{F}^2 - 3/2). \quad (4)$$

Here $a_{HF} = 2.157 \cdot 10^{-7}$ a.u. is the hyperfine constant, $\mathbf{s}_{e,\bar{e}}$ is the electron (positron) spin, $\mathbf{i}_{p,\bar{p}}$ is the proton (antiproton) spin and $\mathbf{F} = \mathbf{s} + \mathbf{i}$ is the total spin of the (pe) or $(\bar{p}\bar{e})$ pair. The above interaction correctly reproduces the ground state hyperfine splitting of separated H and $\bar{H}$ atoms.

The influence of the $(\bar{p}\bar{e})$ or (pe) spin-dependent terms on the spin-exchange reaction rate is expected to be small due to the Coulomb repulsion that prevents the involved particles from approaching each other. We will neglect such terms in our study.

In the case of $(e\bar{e})$ the spin-dependent interaction is responsible for the fine structure and annihilation in Positronium [27]. Due to the CP invariance this interaction conserves spin in Positronium. In our treatment we will use the following simplified model of the $(e\bar{e})$ spin-dependent term:

$$\widehat{W}_{(e\bar{e})} = \alpha^0 \delta(\mathbf{r}_{Ps}) \hat{P}_0 + \alpha^1 \delta(\mathbf{r}_{Ps}) \hat{P}_1. \quad (5)$$

Here α^0 and α^1 are the singlet and triplet interaction constants:

$$\alpha^0 = -4.3 \cdot 10^{-4} - i4.9 \cdot 10^{-6} \text{ a.u.}, \quad (6)$$

$$\alpha^1 = 3.3 \cdot 10^{-4} - i4.3 \cdot 10^{-9} \text{ a.u.}, \quad (7)$$

$\hat{P}_0 = |S_{Ps} = 0, 0\rangle \langle S_{Ps} = 0, 0|$ and $\hat{P}_1 = \sum_M |S_{Ps} = 1, M\rangle \langle S_{Ps} = 1, M|$ are the projection operators on the subspace of singlet or triplet states of Positronium. The suggested form of interaction conserves spin and correctly reproduces the energy shift and annihilation lifetime of para- and ortho-Positronium. The spin-orbit coupling terms are neglected; we will show below that such terms are not important for the spin-exchange transition rates in the $H - \bar{H}$ system.

The leading contribution to the spin-dependent component of the $(p\bar{p})$ interaction arises from the strong force. Strong interaction is CP invariant and conserves the spin S_{Pn} of Protonium.

Furthermore, this interaction is attractive and localized to distances within $R < R_s$ with $R_s \sim 1$ fm ($1.88 \cdot 10^{-5}$ a.u.). It also includes an absorptive component that is responsible for coupling to the $(p\bar{p})$ annihilation channels.

There are several models of low energy $p\bar{p}$ interaction (see [28] and references therein) that differ in the detailed behavior of spin-dependent potentials. These models, however, give close values for the $p\bar{p}$ strong force singlet and triplet scattering lengths $a_{sc}^{0,1}$. Since the range of strong forces is much shorter compared to that of atomic interaction, it is possible to take into account the strong force effect through an appropriate modification of the boundary condition for the scattering wave function. Such a procedure is based on a knowledge of the strong force scattering lengths only [11, 16]. Indeed, at distances such that $R_s \ll R \ll R_r$ the interaction is dominated by the Coulomb $p\bar{p}$ potential. The wave function of internuclear motion at such distances behaves as a superposition of regular $F_0(pR)$ and irregular $G_0(pR)$ Coulomb solutions, with momentum $p \rightarrow 0$ [16]. The coefficient that mixes these two solutions, the K -matrix element k , is determined by the strong force scattering length according to [29, 16] :

$$k = \tan(\delta_{sc}^{0,1}) = -2\pi M a_{sc}^{0,1}, \quad (8)$$

where M stands for the reduced mass of $p\bar{p}$. We will use the following values of the S -state strong force scattering length [30, 28]:

$$a_{sc}^0 = (1.07 - i1.45) \cdot 10^{-5} \text{ a.u.}, \quad (9)$$

$$a_{sc}^1 = (1.68 - i1.06) \cdot 10^{-5} \text{ a.u.} \quad (10)$$

The corresponding nuclear k -matrix elements become

$$\tan(\delta_{sc}^0) = -0.06 + i0.08, \quad (11)$$

$$\tan(\delta_{sc}^1) = -0.1 + i0.06. \quad (12)$$

In terms of state vectors $|f(R), S_{Pn}\rangle$, $R_s < R \ll R_r$, this result can be formulated as follows:

$$|f(R), S_{Pn}\rangle \sim |F_0(pR), S_{Pn}\rangle + \hat{K} |G_0(pR), S_{Pn}\rangle \quad (13)$$

$$\hat{K} = -2\pi M (a_{sc}^0 \hat{\pi}_0 + a_{sc}^1 \hat{\pi}_1). \quad (14)$$

Here the $\hat{\pi}_{0,1}$ are projection operators on the subspaces of singlet and triplet Protonium states. In this way the effect of strong forces could be taken into account by introducing the K -matrix (14). The latter determines the boundary condition that can be imposed on the wave function in the range $R_s < R \ll R_r$. The effect of the strong force induced boundary condition (14) is equivalent to the action of the zero range potential [31]:

$$\hat{V}_s = \frac{2\pi}{M} (a_{sc}^0 \hat{\pi}_0 + a_{sc}^1 \hat{\pi}_1) \delta(\mathbf{R}) \left(\frac{\partial}{\partial R} R \right). \quad (15)$$

To proceed with the calculation of spin-exchange rates within the effective adiabatic model one needs to find the contribution of all spin-dependent terms (3) to the effective internuclear interaction. We will accommodate these terms to the first order of perturbation theory. To do so we average the spin-dependent interactions that depend on leptonic coordinates over the unperturbed leptonic wave function $\Psi_{e,\bar{e}}(R, \mathbf{r}_e, \mathbf{r}_{\bar{e}})$ (calculated without the account of spin-dependent interactions). Taking into account our assumptions about the spin-dependent terms and their radial dependence, such averaging will involve only the $(e\bar{e})$ interaction:

$$\hat{V}_{e\bar{e}}(R) = \int |\Psi_{e,\bar{e}}(R, \mathbf{r}_e, \mathbf{r}_{\bar{e}})|^2 \hat{W}_{e\bar{e}} d\mathbf{r}_e d\mathbf{r}_{\bar{e}} \quad (16)$$

$$\hat{V}_{e\bar{e}}(R) = A(R) \left(\alpha^0 \hat{P}_0 + \alpha^1 \hat{P}_1 \right), \quad (17)$$

where $A(R) = |\Psi_{e,\bar{e}}(R, \mathbf{r}_e = \mathbf{r}_{\bar{e}})|^2$ is the leptonic coalescence probability. We use the values of the coalescence probability calculated in ref. [11]. The corresponding spin-dependent leptonic

Figure 1: Real part of the spin-dependent leptonic potentials for the singlet (dashed line) and triplet (solid line) states.

potentials for the singlet and triplet states are shown in Fig. 1. We note that the spin-dependent interactions (3) also modify the final states of Pn and Ps in the rearrangement channels, so that the latter may contribute to the effective optical potential $\hat{V}_{opt}$. Such a contribution only arises at the level of second order perturbation theory and will not be taken into account here.

We may now formulate the scattering problem for spin-exchange transitions. The spin state of the colliding $H - \bar{H}$ system can be described in different representations, in terms of 16 spin basis vectors. Since the spin-dependent terms for $(p\bar{p})$ and $(e\bar{e})$ interactions conserve spin of the corresponding pairs, they will be diagonal in the basis set with given $(p\bar{p})$ and $(e\bar{e})$ spins. Such basis set will be denoted $|S_{(p,\bar{p})}, M_{(p,\bar{p})}, S_{(e,\bar{e})}, M_{(e,\bar{e})}\rangle$. We will hereafter refer to this basis as the S -representation.

The asymptotic Hamiltonian, which describes the separated H and $\bar{H}$ atoms and includes the hyperfine terms $\hat{W}_{(pe)}$ and $\hat{W}_{(\bar{p}\bar{e})}$, is diagonal in the basis with given (pe) and $(\bar{p}\bar{e})$ spins F_H and $F_{\bar{H}}$, respectively. Such basis set will be denoted $|F_H, M_H, F_{\bar{H}}, M_{\bar{H}}\rangle$ and will be called the F -representation. The scattering state vector $|\varphi\rangle$ is a superposition of basis spin states:

$$|\varphi\rangle = \sum_{F_H, M_H, F_{\bar{H}}, M_{\bar{H}}} f(R)_{F_H, M_H, F_{\bar{H}}, M_{\bar{H}}} |F_H, M_H, F_{\bar{H}}, M_{\bar{H}}\rangle \quad (18)$$

The R -dependent expansion coefficients play the role of hadronic wave functions for the $H\bar{H}$ system in a given spin state of four particles. The asymptotic form of functions $f(R)$ at large R gives in a standard way the S -matrix in the given spin-state representation. The desired wave functions are found from the solution to the coupled equation system:

$$\sum_{\mu} \langle \mu' | \hat{H} - E | \mu \rangle F(R)_{\mu, \eta} = 0, \quad \eta = 1, 2, \dots, 16 \quad (19)$$

Here $F(R)_{\mu', \mu}$ is a 16×16 solution matrix whose indices label the outgoing (μ') and incoming (μ) channels, respectively; and η labels the sets of spin quantum numbers $F_H, M_H, F_{\bar{H}}, M_{\bar{H}}$.

While solving the coupled channel equations we utilize the fact that for interatomic distances $R \sim 1$ a.u. and below the characteristic values of the local adiabatic potential are much greater

than the hyperfine splitting. Thus even in the zero-energy limit the hyperfine terms may be neglected in the solution (19) at short and intermediate internuclear distances. At such distances the equation system can be decoupled in the $|S_{(p,\bar{p})}, M_{(p,\bar{p})}, S_{(e,\bar{e})}, M_{(e,\bar{e})}\rangle$ basis:

$$\left(-\frac{1}{2M}\frac{d^2}{dR^2} + \hat{V}_{opt} + V_{ad}(R) + A(R)\alpha^{S_{(e\bar{e})}} - E\right) F(R)_{\mu,\mu} = 0, \quad (20)$$

where μ denotes a set of quantum numbers $S_{(p,\bar{p})}, M_{(p,\bar{p})}, S_{(e,\bar{e})}, M_{(e,\bar{e})}$. Such an equation system should be supplied with boundary conditions, imposed at arbitrary R_0 within the range $R_s \ll R_0 \ll R_r$, and specified by the strong force K -matrix (14):

$$F(R_0)_{\mu,\mu'} = \delta_{\mu,\mu'} \left(F_0(pR_0) - 2\pi a_{sc}^{S_{(p\bar{p})}} G_0(pR_0) \right) \quad (21)$$

$$F'(R_0)_{\mu,\mu'} = \delta_{\mu,\mu'} \left(F'_0(pR_0) - 2\pi a_{sc}^{S_{(p\bar{p})}} G'_0(pR_0) \right). \quad (22)$$

Instead of solving the equation system (20) with the boundary conditions (21-22) we use the more practical method developed in [16]. It amounts to introducing specially fitted boundary conditions at the *rearrangement radius* $R = R_r$:

$$(F'(R_r)F^{-1}(R_r))_{\mu,\mu'} = \delta_{\mu,\mu'} p(R_r) \cot(\delta + \delta_{sc}^{S_{(p\bar{p})}}) \quad (23)$$

where $p(R_r) = \sqrt{2MV_{ad}(R_r)}$ is a classical local momentum given at the internuclear separation R_r . The phase shift δ takes into account the effect of the optical and adiabatic potentials accumulated at distances below R_r . The account of strong forces is achieved by adding to the phase shift δ the spin dependent strong force phase shift $\delta_{sc}^{S_{(p\bar{p})}}$. The additivity of phases is explained by the fact that contribution of the optical potential to the phase shift is vanishing in the region $R < R_s$, characteristic for strong forces. The phase shift δ is calculated using the model nonlocal optical potential [16] and is given by:

$$\delta = 0.74 + i0.32. \quad (24)$$

The advantage of the above method is that once the phase shift δ is calculated, the effect of rearrangement transitions is incorporated through the boundary condition (23) obviating cumbersome calculations with nonlocal potentials. The phase shift approach gives a useful universal tool for the treatment and analysis of rearrangement transitions.

Once the (decoupled) equation system is solved in the S -representation, the solutions (valid in the limited range below $R \sim 1$ a.u.) should be transformed back to the asymptotically correct F -representation. This is done by means of a unitary transformation [19]:

$$\tilde{F}(R) = U^+ F(R) U \quad (25)$$

$$U = \langle S_{(p,\bar{p})}, M_{(p,\bar{p})}, S_{(e,\bar{e})}, M_{(e,\bar{e})} | F_H, M_H, F_{\bar{H}}, M_{\bar{H}} \rangle \quad (26)$$

Thus obtained solution $\tilde{F}(R)$ should be matched at some point $R_0 \sim 1$ a.u. with a solution Φ , in which now the hyperfine energy splitting is taken into account:

$$\sum_{\mu} \left[\left(-\frac{1}{2M} \frac{d^2}{dR^2} + V_{ad}(R) \right) \delta_{\mu',\mu} + [U^+ \hat{V}_{(e\bar{e})} U]_{\mu',\mu} + Q_{\mu',\mu} \right] \Phi_{\mu,\eta}(R) = E \Phi_{\mu',\eta} \quad (27)$$

$$[\tilde{F}'(R_0) \tilde{F}^{-1}(R_0)]_{\mu',\mu} = [\Phi'(R_0) \Phi^{-1}(R_0)]_{\mu',\mu}. \quad (28)$$

Here $Q_{\mu',\mu}$ is a diagonal (16×16) hyperfine energy matrix, which gives the threshold energies in channels with different combinations of total spin F_H and $F_{\bar{H}}$. Its diagonal values are:

Figure 2: The spin-exchange cross sections $\sigma_{d\bar{a} \rightarrow a\bar{d}}$ (solid line) and $\sigma_{d\bar{a} \rightarrow c\bar{d}}$ (dashed line).

$$Q_{\mu,\mu} = \alpha_{HF} \begin{cases} 0 & \text{if } (F_H = 0, F_{\bar{H}} = 0) \\ 1 & \text{if } (F_H = 1, F_{\bar{H}} = 0) \text{ or } (F_H = 0, F_{\bar{H}} = 1) \\ 2 & \text{if } (F_H = 1, F_{\bar{H}} = 1) \end{cases} \quad (29)$$

From the conservation of the projection of total spin ($M_{H\bar{H}} = M_H + M_{\bar{H}}$) it follows that the Φ -matrix has a block structure, consisting of a 6×6 matrix ($M = 0$), two 4×4 matrixes ($M_{H\bar{H}} = 1$ and $M_{H\bar{H}} = -1$) and two 1×1 matrixes ($M_{H\bar{H}} = 2$ and $M_{H\bar{H}} = -2$).

The such obtained solution matrix has the following asymptotic form as $R \rightarrow \infty$:

$$\Phi(R) \rightarrow \exp(-i\hat{p}R) - \exp(i\hat{p}R)\hat{p}^{-1/2}\hat{S}\hat{p}^{1/2}. \quad (30)$$

Here $\hat{p}$ is a diagonal matrix whose elements are $\hat{p}_{\mu,\mu} = \sqrt{2M(E - Q_{\mu,\mu})}$; $\exp(\mp i\hat{p}R)$ is a diagonal matrix with elements $[\exp(\mp i\hat{p}R)]_{\mu,\mu} = \exp(\mp i\hat{p}_{\mu,\mu}R)$; and $\hat{S}$ is the desired S -matrix.

3 Results and discussion

We consider the $H - \bar{H}$ collisions in the absence of an external magnetic field ($B = 0$). We follow the usual notation for the hyperfine states, i.e. the H state $|F_H = 0, M_H = 0\rangle$ is denoted as a , the state $|F_H = 1, M_H = -1\rangle$ is denoted b , the state $|F_H = 1, M_H = 0\rangle$ is denoted as c and the state $|F_H = 1, M_H = 1\rangle$ is denoted d . The corresponding spin-states of $\bar{H}$ are denoted $\bar{a}$, $\bar{b}$, $\bar{c}$ and $\bar{d}$. We present three types of typical behavior of spin exchange cross sections as a function of collision energy. The spin-exchange cross sections $\sigma_{d\bar{a} \rightarrow a\bar{d}}$ and $\sigma_{d\bar{a} \rightarrow c\bar{d}}$ are shown on Fig. 2; the cross section $\sigma_{c\bar{d} \rightarrow d\bar{a}}$ is shown on Fig. 3.

According to the CPT invariance, the energies of the $d\bar{a}$ and $a\bar{d}$ states are equal and so the reaction $d\bar{a} \rightarrow a\bar{d}$ takes place even in the limit of vanishing collision energy, $E \rightarrow 0$. In that limit the cross section tends to a constant value, $\sigma_{d\bar{a} \rightarrow a\bar{d}}(E) \rightarrow 0.04 \text{ a.u.}^2$.

The reaction $d\bar{a} \rightarrow c\bar{d}$ can only occur above the threshold energy $Q_{d\bar{a} \rightarrow c\bar{d}} = \alpha_{HF}$. The threshold behavior of the associated cross section is clearly seen on Fig. 2. Again, according to the CPT invariance, the cross sections for conjugated reactions are the same, giving $\sigma_{d\bar{a} \rightarrow c\bar{d}} = \sigma_{a\bar{d} \rightarrow d\bar{c}}$. The inverse reaction $c\bar{d} \rightarrow d\bar{a}$ is exothermic (in our case the energies of the final

Figure 3: The spin-exchange cross section $\sigma_{cd \rightarrow d\bar{a}}$.

states for exothermic reactions are smaller than the energies of the initial states by α_{HF} or $2\alpha_{HF}$) so that the cross section varies as $1/v$, where v is the incident channel velocity. Such behavior is shown in Fig. 3. Hence, for collisional energies $E < \alpha_{HF}$ the cross sections of exothermic reactions are the largest among spin-exchange cross sections. Let us mention that a hypothetical violation of CPT invariance would manifest itself in a radical change of the spin-exchange cross sections. In particular, the energy difference between the hyperfine levels of H and $\bar{H}$ (induced by the CPT violation) would result in the appearance of new reaction thresholds. Consequently, the cross sections of the reactions $d\bar{a} \rightleftharpoons a\bar{d}$ would follow the above mentioned (v and $1/v$) threshold pattern, instead of tending to the established constant value in the limit $E \rightarrow 0$.

For increasing collision energies, i.e. when $E \gg \alpha_{HF}$, all spin-exchange cross sections tend to the same limit. In such a case the hyperfine splitting can be neglected even in the asymptotic states. Therefore the S -matrix is diagonal in S -representation. The S -matrix in the F -representation (needed in our calculation of cross sections) is obtained by the transformation specified in eq. (26). One can show (using the explicit form of the transformation matrix U [19]) that the S -matrix elements in the F -representation for the reactions $d\bar{a} \rightarrow a\bar{d}$ and $d\bar{a} \rightarrow c\bar{d}$, are connected to the matrix elements in the S -representation in the following way:

$$S_{d\bar{a} \rightarrow a\bar{d}} = \frac{(\langle 0, 1 | S | 0, 1 \rangle + \langle 1, 0 | S | 1, 0 \rangle)}{4} - \frac{\langle 1, 1 | S | 1, 1 \rangle}{2}, \quad (31)$$

$$S_{d\bar{a} \rightarrow c\bar{d}} = \frac{(\langle 0, 1 | S | 0, 1 \rangle - \langle 1, 0 | S | 1, 0 \rangle)}{4}. \quad (32)$$

Here $\langle i, j | S | i, j \rangle$ is the S -matrix element in the S -representation, with $S_{p\bar{p}} = i$ and $S_{e\bar{e}} = j$ ($i, j = 0, 1$). It follows from (31, 32) that the equality of cross sections $\sigma_{d\bar{a} \rightarrow a\bar{d}} = \sigma_{d\bar{a} \rightarrow c\bar{d}}$ requires:

$$\langle 1, 0 | S | 1, 0 \rangle = \langle 1, 1 | S | 1, 1 \rangle. \quad (33)$$

The above equality means that the elastic scattering in the state $|S_{p\bar{p}} = 1, S_{e\bar{e}} = 0\rangle$ is the same as in the state $|S_{p\bar{p}} = 1, S_{e\bar{e}} = 1\rangle$. This can hold if the contribution of the $(e\bar{e})$ spin-dependent potential (17) is negligible. A calculation made without the inclusion of the

potential (17) fully confirmed this assertion. The scattering lengths a_{10} and a_{11} in the states $|S_{p\bar{p}} = 1, S_{e\bar{e}} = 0\rangle$ and $|S_{p\bar{p}} = 1, S_{e\bar{e}} = 1\rangle$ turned out to be:

$$a_{10} = 5.665 - i2.216 \text{ a.u.} \quad (34)$$

$$a_{11} = 5.677 - i2.216 \text{ a.u.} \quad (35)$$

while the scattering length a_1 , calculated without inclusion of the potential (17) turned out to be:

$$a_1 = 5.666 - i2.216 \text{ a.u.}$$

The small difference between these scattering lengths proves that the role of spin-dependent $e\bar{e}$ interaction is negligible. To understand this we note that the ratio $|V_{e\bar{e}}(R)/V_{ad}(R)|$ never exceeds 10^{-3} and reaches a maximum in the range $3 \text{ a.u.} < R < 5 \text{ a.u.}$. At these distances the WKB approximation is still justified. The semiclassical phase accumulated at these distances by the wave function (without account of the $V_{e\bar{e}}(R)$) is:

$$\delta_{WKB} = \int_{R_1}^{R_2} \sqrt{2M|V_{ad}(r)|} dr.$$

The change of that phase due to the account of spin-dependent leptonic potential $V_{e\bar{e}}(R)$ is :

$$\Delta\delta_{WKB} = \int_{R_1}^{R_2} \frac{\sqrt{M}V_{e\bar{e}}(R)}{\sqrt{2|V_{ad}(R)|}} dr < 10^{-3} \frac{\delta_{WKB}}{2}$$

which explains the small contribution of the leptonic spin-dependent interaction to the phase of the wave function, and therefore to the S -matrix [16]. Thus we come to the conclusion that the rate of spin-exchange in $H - \bar{H}$ collisions is determined *by the $p\bar{p}$ strong interaction*.

The short-range character of strong forces enables the factorization of nuclear and atomic interactions and simplifies the study of the energy dependence of the spin-exchange cross sections. At short distances, where spin transitions take place, the energy difference between the final states can be totally neglected. Using the explicit form of the transition matrix U (26) and the zero-range pseudo-potential (15) one can get the transition amplitude between different spin states in the distorted wave approximation:

$$f_{\alpha\beta} = \frac{a_{sc}^1 - a_{sc}^0}{4} \int \Psi_{\beta}^{0*}(\mathbf{R}) \delta(\mathbf{R}) \left(\frac{\partial}{\partial R} R \right) \Psi_{\alpha}^0(\mathbf{R}) d^3 R = \frac{a_{sc}^1 - a_{sc}^0}{4} \Psi_{\beta}^{0*}(0) \Psi_{\alpha}^0(0). \quad (36)$$

Here $\Psi_{\alpha,\beta}^0(\mathbf{R})$ is the wave function corresponding the initial (final) spin-state α (β), calculated without taking strong forces into account. (We note that the exact expression for the transition amplitude can be obtained from (36) upon replacing $\Psi_{\alpha,\beta}^0(\mathbf{R})$ by the wave function calculated with the account of strong forces.) The only contribution to the spin-exchange amplitude arises from the S -wave, since the higher partial wave functions tend to zero at the origin. The spin exchange cross section is then given by the following expression:

$$\sigma_{\alpha\beta} = \pi \frac{p_{\beta}}{p_{\alpha}} \frac{|a_{sc}^1 - a_{sc}^0|^2}{4} |\Psi_{\beta}^0(0) \Psi_{\alpha}^0(0)|^2, \quad (37)$$

where $p_{\alpha,\beta}$ is the channel momentum. It is convenient to perform a further analysis in terms of the Jost function f_J . Following the definition of the S -wave Jost function [32] we may for our case write

$$\Psi_{\alpha}^0(\mathbf{R}) = \frac{\phi_{\alpha}^0(R)}{R f_J(p_{\alpha})} \quad (38)$$

where $\phi_{\alpha}^0(R)$ is the regular S -wave radial solution of the Schrödinger equation (neglecting strong forces) in spin-state α . The behavior of the regular solution at the origin is

$$\phi_{\alpha}^0(R \rightarrow 0) = R$$

so that

$$\Psi_\alpha^0(0) = \frac{1}{f_J(p_\alpha)}. \quad (39)$$

Equation (37) now takes the form:

$$\sigma_{\alpha\beta} = \pi \frac{p_\beta}{p_\alpha} \left| \frac{a_{sc}^1 - a_{sc}^0}{2f_J(p_\beta)f_J(p_\alpha)} \right|^2. \quad (40)$$

Near the threshold the momentum dependence of the Jost-function is known to be [32]:

$$f_J(p_\alpha) = f_J(0) \exp(-ip_\alpha a) \quad (41)$$

where a is the atom-antiatom scattering length (without the account of strong forces). Numerical calculations give the following values for a and $1/|f_J(0)|^2$:

$$a = 5.2 - i1.8 \text{ a.u.} \quad (42)$$

$$1/|f_J(0)|^2 = 29067. \quad (43)$$

We can exploit the smallness of the energy thresholds (determined by the hyperfine constant α_{HF}) in different spin states, and get for the near-threshold behavior of the spin-exchange cross section:

$$\sigma_{\alpha\beta} = \pi \frac{p_\beta}{p_\alpha} \exp(2 \operatorname{Im} a(p_\alpha + p_\beta)) \left| \frac{a_{sc}^1 - a_{sc}^0}{2f_J^2(0)} \right|^2. \quad (44)$$

It follows from the above formula that, in the case $p_\alpha = p_\beta$, the cross section in the zero-energy limit tends to the constant value:

$$\sigma_0 = \pi \left| \frac{a_{sc}^1 - a_{sc}^0}{2f_J^2(0)} \right|^2 = 0.04 \text{ a.u.} \quad (45)$$

while in the presence of the energy threshold the behavior of the cross section is determined by the imaginary part $\operatorname{Im} a$ of the atom-antiatom scattering length:

$$\sigma_{\alpha\beta} = \frac{p_\beta}{p_\alpha} \exp(2 \operatorname{Im} a(p_\alpha + p_\beta)) \sigma_0. \quad (46)$$

Comparison of the above expression, obtained in the distorted wave approximation, with the results of numerical calculations, shows that the formula (46) is accurate to within a few percent for collision energies below 10^{-5} a.u.

The behavior of the cross section (46) near the threshold has a clear physical meaning. Spin-exchange can only occur when the nuclei approach distances characteristic for strong forces, i.e. 1 fm. Due to inelastic rearrangement transitions into the $Pn + Ps$ channels the flux of $H - \bar{H}$ at such distances is damped by the factor $\exp(2 \operatorname{Im} a(p_\alpha + p_\beta))$. The damping rate is given by the imaginary part of scattering length for $H - \bar{H}$ collisions. We note that the imaginary part of the scattering length can be extracted from the energy dependence of the spin-exchange cross sections [33].

In the case of exothermic reactions (e.g. $c\bar{d} \rightarrow d\bar{a}$ or $b\bar{d} \rightarrow a\bar{a}$) there is an energy excess in the final channel: $\Delta E_\beta = n\alpha_{HF}$, $n = 1, 2$. It follows from (46) that the cross sections for such reactions behave like d_n/v in the limit $E \rightarrow 0$. Taking into account that as $E \rightarrow 0$ $p_\beta \rightarrow \sqrt{2Mn\alpha_{HF}}$, we obtain for d_n :

$$d_n = \frac{\sqrt{2Mn\alpha_{HF}}}{M} \exp(2 \operatorname{Im} a \sqrt{2Mn\alpha_{HF}}) \sigma_0, \quad (47)$$

which gives:

$$d_1 = 8.0 \times 10^{-7} \text{ a.u.}^2 \quad (48)$$

$$d_2 = 1.1 \times 10^{-6} \text{ a.u.}^2 \quad (49)$$

The ratio of the near-threshold spin-exchange reaction rates $b\bar{d} \rightarrow a\bar{a}$ and $c\bar{d} \rightarrow d\bar{a}$ is given by:

$$d_2/d_1 = \sqrt{2} \exp\left(2(\sqrt{2}-1) \operatorname{Im} a \sqrt{2M\alpha_{HF}}\right) = 1.375. \quad (50)$$

As one can see, this ratio is determined by the product $\operatorname{Im} a \sqrt{2M\alpha_{HF}}$.

The cross sections of the inverse reactions ($d\bar{a} \rightarrow c\bar{d}$ or $a\bar{a} \rightarrow b\bar{d}$) show a characteristic threshold behavior. In the vicinity of the threshold they behave like $pd_n/\sqrt{2Mn\alpha_{HF}}$.

It was already mentioned that for $E \gg \alpha_{HF}$ all the spin-exchange cross sections tend to the same limit. Within the zero-range potential model of strong forces, this limit is given by:

$$\sigma = \exp(4 \operatorname{Im} ap) \sigma_0. \quad (51)$$

A remarkable feature of the obtained results is the factorization of the spin-dependent strong force effect and the effect of long-range atomic interaction (44). While the first appears through the difference between singlet and triplet *strong force* scattering lengths, the second is given by the Jost function for the interatomic motion of the $H - \bar{H}$ pair. This latter factor ($|1/f_J(0)|^4$) strongly enhances (approximately 10^9 times!) the effect of strong forces, due to focusing of the flux of $p - \bar{p}$ towards the center by the molecular potential. The large value of the enhancement factor is determined by the large ratio between atomic and nuclear scales.

Under certain conditions, the enhancement factor $|1/f_J(0)|^4$ could become even larger. This additional enhancement is due to the existence of the near-threshold quasi-molecular $H\bar{H}$ states [16]. Indeed, such quasi-bound states manifest themselves as zeros of the Jost function $f_J(p)$ in the complex momentum plane. The presence of these zeros in the threshold vicinity leads to a small value for $f_J(0)$. To study the question in more detail we will use the analytical expression for the Jost function based on the WKB approximation for interatomic motion at distances $1 \text{ a.u.} < R < 5 \text{ a.u.}$ (see Appendix):

$$\frac{1}{|f_J^{WKB}(0)|^2} = \frac{2\pi M a_0}{\sin^2(\pi/8 + \Omega + \delta)}. \quad (52)$$

In the above equation, a_0 is the characteristic scale for van der Waals interaction between H and $\bar{H}$ [16]:

$$a_0 = \sqrt[4]{2MC_6} \frac{\Gamma(3/4)}{2\sqrt{2}\Gamma(5/4)} \simeq 4.99 \text{ a.u.} \quad (53)$$

$C_6 = 6.5$ is the van der Waals constant for $H\bar{H}$ interaction, Ω is the semiclassical phase, accumulated in the distance range $R > R_r$

$$\Omega = \int_{R_r}^{\infty} \sqrt{2MV_{ad}(R)} dR = 19.38 \quad (54)$$

and $\delta = 0.74 + i0.32$ is the *complex* phase shift (24) accumulated at distances less than R_r . The value of expression (52), obtained within the WKB approximation, turns out to be

$$\frac{1}{|f_J^{WKB}(0)|^2} = 24\,830 \quad (55)$$

and is comparatively close to the exact value (43).

Following the method developed in [16], we will vary the total phase of the wave function $\varphi = \pi/8 + \delta + \Omega$. The physical sense of such procedure is the following. It is known that interatomic interactions can be modified by means of external magnetic or electric fields (see [34, 35] and references therein). Without specifying the physical method of such modification we may describe the resulting effect as a variation of the accumulated phase of the wave function. We will be interested in such modification of interatomic interaction that results in the increase of the enhancement factor (43). This factor (43) would become infinite (the Jost function $f_J(0) = 0$) if there is a quasi-molecular state exactly at the threshold. In such a case $\varphi = \pi k$,

Figure 4: The zero-energy limit of the $c\bar{d} \rightarrow d\bar{c}$ cross section as a function of the phase variation that expresses a modification of the interatomic interaction due to the presence of an external field.

$k = 0, 1, 2, \dots$. As long as there is an imaginary component of the total phase φ (which represents absorption of the $H - \bar{H}$ flux into rearrangement channels) such a condition can not be satisfied exactly; however the enhancement factor will show maxima corresponding to values of the total phase satisfying $\text{Re } \varphi = \pi k$. As was shown in [16] this condition corresponds to the appearance of decaying quasi-bound state in the spectrum of the $H\bar{H}$ system close to the dissociation threshold.

In Fig. 4 we present the zero-energy limit of the cross section for the reaction $c\bar{d} \rightarrow d\bar{c}$ as a function of phase variation. For certain values of the total phase φ the spin-exchange cross section increases more than 50 times in comparison with its "unbiased" value ($\varphi = 20.51 + i3.2$) obtained in the absence of any external perturbation. Strictly speaking, in such a resonant case the distorted wave approximation (36) is not justified and one should substitute the approximate value of $\Psi_{\alpha,\beta}^0(0)$ by the wave function calculated with the account of strong forces. Nevertheless, this result indicates that the modification of the interatomic $H - \bar{H}$ interaction by external fields could in principle strongly increase the spin-exchange cross sections, exposing the effect of strong forces. Such additional enhancement might also occur in collisions with other atoms, due to the sensitivity of the cross sections to the reduced mass of the colliding nuclei [16].

4 Conclusions

We found that the spin-exchange transitions in $H - \bar{H}$ collisions are caused mainly by the strong force. This mechanism of spin-exchange is a unique feature of atom-antiatom interaction, with no counterpart in atom-atom collisions. The corresponding transition amplitudes are proportional to the difference between singlet and triplet strong force scattering lengths. Meanwhile, the cross sections acquire molecular dimensions due to the large enhancement of the strong force effect; this enhancement originates from the presence of long range, atom-antiatom interaction. We have shown that the enhancement factor is on the order of 10^9 .

The energy behavior of the spin-exchange cross sections turns to be sensitive to the difference between hyperfine energy levels in H and $\bar{H}$ (which might occur due to CPT violation). If

such violation were to occur the threshold behavior of the spin-exchange cross sections would be radically different from the CPT invariant case. We present a universal description of the influence of external fields on the $H - \bar{H}$ scattering, which suggests that field-induced modification of the interatomic interaction can additionally enhance (up to 50 times) the spin-exchange cross sections, exposing the strong force effects.

5 Appendix

The present Appendix outlines the derivation of the analytical expression for the Jost function $f_J(0)$ for a zero collision energy of the $H - \bar{H}$ system. We start with the expression for the S -wave scattering length for $H - \bar{H}$, obtained in [16] under the following assumptions. At distances $R > R_r \sim 1$ a.u. the $H - \bar{H}$ interaction is well described by the one-channel, adiabatic potential $V_{ad}(R)$. At distances $R > R_h \sim 5$ a.u. this potential can be accurately reproduced by the van der Waals interaction $-C_6/R^6$, with $C_6 = 6.5$. There exists a domain $R_r < R < R_h \ll R_{vdW}$, with $R_{vdW} = \sqrt[4]{2MC_6} \simeq 10.5$ a.u., where the WKB approximation is well justified.

Matching the WKB wave function to the exactly known asymptotic zero energy solution of the Schrödinger equation with the $-C_6/R^6$ potential, one gets the following expression for the scattering length in $H - \bar{H}$ collisions:

$$a = a_0 \left(1 + \cot\left(\frac{\pi}{8} + \Omega + \delta\right) \right) \quad (56)$$

where a_0 is

$$a_0 = R_{vdW} \frac{\Gamma(3/4)}{2\sqrt{2}\Gamma(5/4)} \simeq 4.99 \text{ a.u.} \quad (57)$$

and $\Omega = 19.38$ is the WKB phase (54), accumulated in the domain $R_r < R < \infty$.

To calculate the Jost function, we determine the variation of the scattering length (56) with the small variation of phase $\Delta\delta$:

$$\Delta a = -a_0 \frac{\Delta\delta}{\sin^2\left(\frac{\pi}{8} + \Omega + \delta\right)}. \quad (58)$$

In the case of the zero-range potential

$$V_{ZRP} = \frac{2\pi}{M} a_{sc} \delta(\mathbf{R}) \left(\frac{\partial}{\partial R} R \right) \quad (59)$$

the variation of phase is given by (8):

$$\Delta\delta = -2\pi M a_{sc}. \quad (60)$$

The corresponding variation of the scattering amplitude, induced by the zero-range potential (59), can be obtained within the distorted wave approximation:

$$\Delta f = -\frac{M}{2\pi} \int \Psi_0(\mathbf{R})^* V_{ZRP} \Psi_0(\mathbf{R}) d^3 R = -a_{sc} |\Psi_0(0)|^2 \quad (61)$$

where $\Psi_0(\mathbf{R})$ is the wave function calculated without the account of the potential (59). We now use eq. (39) to express the wave function in terms of the Jost function and obtain

$$\Delta f = -\frac{a_{sc}}{|f_J(0)|^2}. \quad (62)$$

The S -wave scattering length is connected to the zero-energy scattering amplitude by the relation $a = -f(0)$. Inserting this relation into eq. (62) and comparing (62) with (58), we finally obtain the following expression for $1/|f_J(0)|^2$:

$$1/|f_J(0)|^2 = \frac{2\pi M a_0}{\sin^2(\pi/8 + \Omega + \delta)}. \quad (63)$$
